

Constraining the geometry of the Universe using Type Ia supernovae and statistical methods

Jacky Cao, Group C3, Physics Problem Solving

Date of report: 28/02/2018

Type Ia supernovae have the unique trait of being standard candles, their light curves can be used in cosmology to calculate and constrain cosmological parameters. In observing Type Ia supernovae and fitting model light curves to such data one can attempt to derive such values. We have monitored, collected, and analysed data for supernova explosions over a period of 34 days. A 16'' and a 0.5 m telescope situated in Durham and La Palma was used for this project. After calculating the magnitudes for a Type Ia (2017hhz) and Type Ia-91bg (2017hle) supernova object, we fitted template light curves with the Python program, *SNooPy*. The quality of fit for the program's `fit()` function was deemed to be acceptable in accordance to the average reduced χ^2 values calculated for the B and V photometric bands, $\chi^2_{\nu,B} \approx 1.38$ and $\chi^2_{\nu,V} \approx 2.95$ - a good fit requiring $\chi^2_{\nu} \approx 1$. The distance modulus to the supernova 2017hhz was calculated by *SNooPy* to be 36.121 ± 0.106 mag, using this value we were able to compute $H_0 = 70 \pm 20 \text{ km s}^{-1} \text{ Mpc}^{-1}$. However, the quoted error negates the meaning of H_0 as it is too large of an uncertainty. In improving the accuracy and uncertainties we suggest that more observations of the supernovae were required, and constraining values should be used for the parameters in *SNooPy*'s templates.

I. INTRODUCTION AND THEORY

In cosmology, one can argue that one of the most important observable events are supernova explosions. As a massive main sequence star runs out of nuclear fuel to burn, the equilibrium configurations which initially provided structure will cease to exist. What follows is a cataclysmic supernova explosion [1].

We can generally class supernova explosions into two separate groups, Type I and Type II supernovae. The main distinction arises due to the fact that Type I's have an optical spectra which contains no Balmer hydrogen features, whilst Type II supernovae do contain this hydrogen feature [2].

Within these two subclasses there are further divisions which can be characterised through their spectra and through features as found in their light curves [3]. Light curves are a way to show the evolution of a supernova's magnitude as time passes. For example, with two of the subclasses of Type II supernovae, Type II-L and Type II-P, they can be classed from features of their light curves. For a Type II-L supernova there is a rapid linear decrease in magnitude, and with a Type II-P we see a constant magnitude after maximum [2].

For the application of supernovae in cosmology, we must turn to the variety of Type Ia.

a. Type Ia Supernovae

It is accepted that the light curves of Type Ia supernovae are generally homogeneous [4], this means that they can be utilised as standard candles therefore allowing us a measure of cosmic distance.

Their homogeneity arises due to the mechanism behind the explosion. The progenitor system for Type Ia's consist of a binary system with a primary white dwarf and secondary star which has a mass close towards the Chandrasekhar limit of $1.4M_{\odot}$ [2, 4]. The white dwarf will accrete matter from it's companion until it itself reaches the critical mass limit. After this point we would then expect the primary star to collapse into a neutron star, however this is not what happens. Instead, we find that a supernova explosion occurs. An event which arises due to a massive disruption to the star's internal structure by a large amount of energy. [[give a rough value]]

It is currently understood that as the white dwarf accretes matter it heats up and produces thermonuclear energy. This energy is achieved in the stellar interior at a temperature of 10^9 K , as a result a disruption to the electron degeneracy pressure takes place. The star becomes gravitationally unstable from the nuclear energy and a total collapse into a neutron star is prevented [1, 4].

This particular mechanism can be used to explain the standard profile of Type Ia light curves. Using these plots, the maximum B band photometric magnitude can be obtained with the following equation,

$$M_{\text{max}}(B) = -21.726 + 2.698\Delta m_{15}(B), \quad (1)$$

where $\Delta m_{15}(B)$ is the decline rate parameter or Phillips' parameter [5]. This is defined as the mean rate of decline of the B band light curve from peak light to 15 days after the maximum [6]. This parameter relates the apparent magnitude to time and provides a way to compare and contrast different Type Ia supernovae.

With values for the absolute magnitude of Type Ia supernovae and with values of their redshift obtained from spectroscopic observations, the distance to these objects can then be calculated using the following equation,

$$\mu = 5 \log_{10}(d) - 5, \quad (2)$$

where μ is the distance modulus and can be defined as the absolute magnitude of supernova subtracted from it's apparent magnitude, and we define d is the distance to the supernova in parsecs [2].

From data sets of Type Ia supernovae we can easily employ them to calculate the geometry of the universe. But before that, we must first understand what cosmological parameters are and how they can be constrained.

b. Cosmological Parameters

At large cosmological distances, the appearance of objects will be affected by the spacetime which it travels through. If we therefore wanted to describe the geometrical properties of the universe, we would require to solve Einstein's general theory of relativity. From *An*

Introduction to Modern Astrophysics [2] we can build the framework required to calculate and compute cosmological parameters.

If we solve Einstein's field equations for an isotropic, homogenous universe a description of the evolution of the universe can be obtained in the form of a differential equation which is also known as the Friedmann equation. In the 1922 form of the equation, a non-static universe is accounted for,

$$\left[\left(\frac{1}{R} \frac{dR}{dt}\right)^2 - \frac{8}{3}\pi G\rho\right]R^2 = -kc^2, \quad (3)$$

where $R(t)$ is the scale factor, G the gravitational constant, ρ is the mass density, k is a parameter which describes the shape of the universe, and c is the speed of light in a vacuum.

k can be defined as a constant which is equal to -1 for a negatively curved universe, 0 for a spatially flat universe, and $+1$ for a positively curved universe [1].

Separate work performed by Einstein eventually led to a cosmological constant Λ being introduced in the Friedmann equation. This was included in the form of $\frac{1}{3}\Lambda c^2$ within the square brackets of the left hand side of Equation 3. Whilst Einstein included this term to account for his static and closed universe, as a consequence of observations which implied an accelerating universe, astronomers in the 1990s eventually related the cosmological constant to dark energy.

Taking the Friedmann equation, it can be rewritten so that it considers a three component universe composed of baryonic and dark matter, relativistic photons and neutrinos, and dark energy,

$$\left[\left(\frac{1}{R} \frac{dR}{dt}\right)^2 - \frac{8}{3}\pi G(\rho_M + \rho_r + \rho_\Lambda)\right]R^2 = -kc^2, \quad (4)$$

where ρ_M is the density of matter, ρ_r is the density of the radiation, and ρ_Λ is the density of the dark energy. Combining these densities with a critical density we can adapt the Friedmann equation so that it includes *cosmological parameters*, these are values which describe the content makeup of the universe in terms of matter and energy. This critical density is defined as the value of the density that will result in a flat ($k=0$) universe. We see that the Friedmann equation becomes,

$$H^2[1 - (\Omega_m + \Omega_r + \Omega_\Lambda)]R^2 = -kc^2, \quad (5)$$

where H is the Hubble parameter and is related to the scale factor and expansion factors of the universe, Ω_m is the matter density parameter, Ω_r is density contribution from radiation, and Ω_Λ is defined as the dark energy density parameter.

With this in hand, it is now possible to calculate the proportions of the universe which amounts to matter and the amount which is energy. In these calculations, cosmologists normally choose to omit the contribution from radiation as it is a negligible amount. Results from the Wilkinson Microwave Anisotropy Probe (WMAP) show that $\Omega_{\text{rad}} = 8.25 \times 10^{-5}$, an insignificant value when compared to $\Omega_\Lambda = 0.74 \pm 0.04$ and $\Omega_m = 0.27 \pm 0.04$ [2].

Using these cosmological variables we can additionally define the total density parameter,

$$\Omega \equiv \Omega_m + \Omega_\Lambda + (\Omega_r). \quad (6)$$

Inputting the WMAP data into Equation 6 we see that a value of $\Omega \sim 1$ is produced, indicating that the universe is flat with $k=0$ and that dark energy is the dominant factor in the expansion of the universe [2].

This result was obtained through measurements of the cosmic microwave background, however it would be especially useful if data from other cosmic objects could be used. We therefore return to Type Ia supernovae as they are the perfect candidate to help us constrain the geometry of the universe. They are more readily accessible and observations can be more easily made.

c. Cosmological Parameters from Type Ia Supernovae

To constrain the cosmological parameters using supernovae we do not look at the Friedmann equation directly. Instead, the main methodology is to use a Least Squares test to select the best model which would then correspond to cosmological parameters. We can define this test as the χ^2 statistic,

$$\chi^2 = \sum \frac{(f_{\text{obs}} - f_{\text{model}})^2}{\sigma_{\text{obs}}^2}, \quad (7)$$

where f_{obs} is the peak observed flux of the supernova, f_{model} is the model flux for the supernova calculated using the corresponding redshift and with certain defined cosmological parameters, and σ_{model} is the uncertainty on the observational flux [7].

Obtaining f_{obs} is a simple matter, we can find it by using a rearranged form of,

$$m_{\text{obs}} = m_0 - 2.5 \log_{10}(f_{\text{obs}}), \quad (8)$$

that is, m_{obs} is the effective peak magnitude of the supernova, m_0 is the instrumental zero point constant with a value of -20.45 , and f is the supernova flux in units of $\text{erg cm}^{-2}\text{s}^{-1}\text{\AA}^{-1}$ [7].

On the other hand, to find f_{model} we begin by defining the flux equation for a certain model,

$$f_{\text{model}} = \frac{L_{\text{peak}}}{4\pi[R_0S(\eta)]^2(1+z)^2}, \quad (9)$$

where L_{peak} is the peak luminosity value for Type Ia supernovae, $R_0S(\eta)$ is the comoving distance between the observer and where the supernova exploded in space, and z is the redshift for the supernova [7].

To find L_{peak} , the low-redshift ($z < 0.1$) Type Ia supernovae objects can be selected out of a data set and then Equation 9 can be used by taking the approximation $R_0S(\eta) \approx cz/H_0$. Optimum L_{peak} can then found by using Equation 7, the smallest value for χ^2 corresponds to the best luminosity. This value can then be applied to calculations involving supernovae which have redshifts higher than 0.1. For this data set the comoving distance cannot be simply approximated so we must use the following definition,

$$R_0\eta = c \int_0^z \frac{dz'}{H(z')}, \quad (10)$$

we find that within this integral we need to integrate a form of the Friedmann equation between a value for the redshift of the supernova z and no redshift. We can derive this by using Equation 5 and with the assumption that if the universe is flat then $\Omega_m = 1 - \Omega_\Lambda$,

reducing the cosmological parameters which we have to find [7].

We now arrive at the following result for the Hubble Parameter,

$$H^2 = H_0^2[(1+z)^3 - \Omega_\Lambda((1+z)^3 - 1)], \quad (11)$$

where H_0 is a value for the Hubble's constant, z is the redshift for a supernova, and Ω_Λ is a cosmological constant.

To find the optimum value for Ω_Λ we can select a range from 0.0 to 1.0 and then calculate f_{model} and χ^2 for each number. Identical to finding L_{peak} , the best value for the cosmological parameter is found by choosing the minimum value for χ^2 . Through the usage of this least squares method one is able to explore cosmological parameters using Type Ia supernova data sets.

d. Project Aims

In this paper we discuss the experimental work performed to constrain cosmological parameters using Type Ia supernova data. Least Squares and Bayesian methods are initially explored, then details of experiments involving models which contain more than two parameters are analysed.

II. RESULTS AND DISCUSSION

a. Least Square Statistics

To calculate cosmological parameters using supernovae we must first obtain data sets of Type Ia supernovae which contain redshift, effective magnitude and the uncertainty on that magnitude. We specify effective magnitude as this means that it has been correct for light curve stretching and galactic dust extinction amongst other factors [7]. This means that the magnitudes used in our calculations will be more accurate and thus produce more accurate parameters.

In our first experiments we chose to use a data set of 42 high-redshift ($z > 0.1$) Type Ia supernovae from the Supernova Cosmology Project (SCP) and 18 low-redshift ($z < 0.1$) ones from the Calán Tololo Survey (CTS) [8]. As indicated in our previous discussion of the experimental theory we require the low-redshift supernovae to 'calibrate' the Type Ia data so that Equation 9 can be used. From Table I we see that we find $L_{\text{peak}} = (3.1 \pm 0.1) \times 10^{35}$ W for the peak luminosity using the SCP and CTS data.

With this we found a corresponding Ω_Λ to be 0.86 ± 0.04 . Comparing it to a literature value of $0.761^{+0.017}_{-0.018}$ [9] we find that there is only a $\sim 10\%$ difference between them. One can gather that whilst our result is consistent with known values, within its own uncertainties it does not include the accurate value. This potentially could be the case because we calculated our χ^2 values in what is known as *flux*-space. Equation 7 uses the observational and model fluxes of the supernovae to calculate the χ^2 values. Instead of this, magnitudes could be used which would shift us into *magnitude*-space. In our investigations we attempted to recalculate Ω_Λ and found 0.71 ± 0.04 , we see that this is more consistent to the given literature value.

Whilst we could have performed the rest of our experiment in magnitude-space, we chose not to as there would be additional implications and uncertainties.

In converting from fluxes into magnitudes using Equation 8 we find that the transformation modifies the input flux distribution and the shape of it will be biased towards fainter magnitudes [10]. However this does not account for the disparity between our calculated cosmological constants.

Investigating this further in literature, we have not been able to find the reason for this disparity. Although we could suggest that it may arise due to the conversion of flux into magnitude for the model in magnitude-space. If we consider observational data for supernovae, we find that multiple steps are required to convert an image into a magnitude value. First of all, frames are taken by CCDs and then aperture or point-spread function photometry is used to measure the amount of flux being received from the object. This flux then has to be converted into a magnitude using Equation 8, where the zero point is found by using objects from the same frame.

In our work we have kept $m_0 = -20.45$, a value which is constant no matter which supernova we are working with. If we were to change it to a more suitable value, would this produce more accurate results? Whilst this possibly could be the case, in our later research with larger data sets we found that working in flux-space returns cosmological parameters which are consistent to measured values. This discrepancy between flux and magnitude-space could simply be eliminated by using a larger data set to constrain the variables, a topic which could be further researched.

But now we turn to look solely at using a larger data set in flux-space, from Table I we find our value for $\Omega_\Lambda = 0.74 \pm 0.01$. We see that it is a $\sim 3\%$ difference between it and the literature value suggesting that using a larger collection of Type Ia supernovae does help to produce a more accurate result. The data set used is the Union2.1 Compilation from the SCP [11], it contains 753 Type Ia supernovae which should be able to provide us with a more accurate calculation when we use the Least Squares method.

FIG. 1: Hubble diagram showing the Union2.1 Type Ia supernova data plotted alongside two models. The blue line represents a universe with $\Omega_{\Lambda,1} = 0.86 \pm 0.04$ and the red line $\Omega_{\Lambda,2} = 0.74 \pm 0.01$. From reduced χ^2 analysis the former parameter appears to be the best fit with $\chi^2_{\nu,1} = 2.4539$ and $\chi^2_{\nu,2} = 2.4547$ respectively. We note that there are too many points for the majority of magnitude error bars to be seen.

Parameter	$\chi_1^2(f)$	$\chi_1^2(m)$	χ_2^2	QCDM	Literature
L_{peak} (W)	$(3.1 \pm 0.1) \times 10^{35}$	$(3.3 \pm 0.1) \times 10^{35}$	$(2.94 \pm 0.04) \times 10^{35}$	$(3.4 \pm 0.1) \times 10^{35}$	-
Ω_Λ	0.86 ± 0.04	0.71 ± 0.04	0.74 ± 0.01	0.73 ± 0.01	$0.761^{+0.017}_{-0.018}$
Ω_k	-	-	-	-0.0029 ± 0.009	$-0.0030^{+0.0095}_{-0.0102}$
Ω_m	-	-	-	0.20 ± 0.02	$0.239^{+0.018}_{-0.017}$
Ω_r	-	-	-	$(4.4 \pm 0.7) \times 10^{-6}$	$(4.16) \times 10^{-6}$
w	-	-	-	-0.912 ± 0.01	$-0.941^{+0.087}_{-0.101}$

TABLE I: Cosmological parameters have been calculated using different data sets and methods. $\chi_1^2(f)$ calculated parameters using the least squares method with the SCP and Calán Tololo Survey data in *flux*-space, and $\chi_1^2(m)$ used *magnitude*-space. χ_2^2 are the parameters found with least squares and the larger Union2.1 SCP data set. QCDM corresponds to the parameters calculated using a variant of the Markov Chain Monte Carlo method and we employ the Quintessence Cold Dark Matter model. We additionally provide literature values which have been obtained from M. Tegmark et al (2006) [9]. We see that as the experiment develops to using different models and analytical methods, the cosmological parameters improve in accuracy.

In Figure 1 we have plotted the Union2.1 data set alongside two models which make use of the calculated cosmological parameters from flux-space. To assess the quality of fit between the data and the model we have calculated reduced χ^2 values. For the model which makes use of $\Omega_{\Lambda,1} = 0.86 \pm 0.04$ we find $\chi_{\nu,1}^2 = 2.4539$, and for the secondary model which uses $\Omega_{\Lambda,2} = 0.71 \pm 0.01$ we proceed to calculate $\chi_{\nu,2}^2 = 2.4547$. The criteria for a model to be a good fit to the data is to produce a reduced χ^2 which is ~ 1 [12]. We therefore would be justified to conclude that $\Omega_{\Lambda,1}$ should be the accepted cosmological constant as it is a closer value to unity, even if it is not consistent with the literature value. However, between both χ_{ν}^2 's there is only a 0.03% difference and we can see from the figure that they are extremely similar. For that reason we could not form a convincing conclusion based on this analysis, instead we decided to explore Bayesian statistics in an attempt to see if the same results could be replicated and whether the accuracy could be improved.

b. Bayesian Statistics

With our work in Bayesian statistics we have primarily made use of the Markov Chain Monte Carlo (MCMC) set of methods. Bayes theorem associates the posterior probability (the probability for parameters given known and observed data) to the likelihood (the probability for the data given certain parameters) and the prior (what was known about the parameter before the data). With these statistical procedures we are in essence updating our information about a value from the prior to the posterior [13]. MCMC makes use of this theory and applies it into a methodology, values are generated and then assigned a likelihood probability, criteria is then used to decide if the parameters should be accepted or not, then finally an optimum solution should be found from all the runs.

For our use in constraining cosmological parameters we chose to utilise a Random Walk Metropolis-Hastings (RWHM) algorithm, the method for which can be found in Appendix B. We chose to use this as it independently samples the parameter space, information about it's current point will not be considered for the location of it's next 'jump' [13]. Instead, an acceptance probability and a random value is compared to generate the next point in the parameter search.

Accurate values are therefore expected with this al-

gorithm, but due to it's statistical nature we are required to perform multiple runs of the same number of walks and then average the optimum values from each run to find the overall optima.

To find solely Ω_Λ we carried out 10 runs of 1500 walks each, from this we found a value of 0.72 ± 0.01 . Whilst this does agree with literature, we must admit that the numbers calculated with least squares method is more accurate. This could be the case due to the number of walks given to the algorithm in a single run, if 10,000 walks had been allocated could we have seen the final optimum match more closely to literature? The answer would most probably be no as the search would have been trapped in a 'local minima' and it could take many walks before it is able to escape.

In our early experiments we consistently became confined in these wells, we would find a value such as $\Omega_\Lambda = 0.47 \pm 0.02$, which is drastically different to what we have found previously. We can see in Figure 2 the dynamics of what occurs. The red dot signifies the initial search parameters for each individual run, for all of our experiments we have allowed this to be $\Omega_\Lambda = 0.80$ and $L_{\text{peak}} = 3.40 \times 10^{35}$. With all of 10 our runs we would manage to produce optimums which were within the vicinity of $\Omega_\Lambda \approx 0.4$ and $L_{\text{peak}} \approx 2.9 \times 10^{35}$. There was a bias towards these values, we can see that the majority of the generated numbers were within 1 or 2 standard deviations of the optima.

We could have circumnavigated this problem by implementing *simulated annealing*, where the descent algorithm is modified by adding random ascent moves so that local minima can always be escaped [14]. In our experimentation we decided to not implement this, instead we chose to avoid local minima by limiting the range of values that the cosmological values could take - we restricted the available parameter space so it would not be trapped.

c. Multi-cosmological Parameters

We now decided to see what kind of results searching for multiple cosmological parameters would bring, an important test as the universe can be described by multiple cosmological parameters. Therefore we turned to the Lambda Cold Dark Matter model (Λ CDM) where a proportion of the universe is made up of cold dark matter and vacuum energy [2, 15] and the geometry behaves slightly differently.

In Λ CDM the cosmic expansion history $H(z)$ can be

FIG. 2: Random Walk Metropolis-Hastings algorithm shown when constraining Ω_Λ and L_{peak} . 10 independent runs performed with 1500 individual random walks for each run. The red dot is the initial provided search parameters $\Omega_\Lambda = 0.8$ and $L_{\text{peak}} = 3.40 \times 10^{35}$, the blue dots represent the optimums for each of the 10 runs, and the green dot is the final average of all of the optimum parameters from each run. The ellipses represent the spread of data with the inner ellipse as 1σ , second as 2σ , and the third as 3σ . This plot shows us the potential for the algorithm to become stuck within local minima if left unconstrained.

given by,

$$H(z) = H_0[X(z)\Omega_\Lambda + (1+z)^2\Omega_k + (1+z)^3\Omega_m + (1+z)^4\Omega_r]^{1/2}, \quad (12)$$

where $X(z)$ is the dark energy density relative to its present value, Ω_k is the spatial curvature of the universe, and the other terms are as previously defined in Section I b [9].

Parameter	$X(z) = 1$	Literature
L_{peak} (W)	$(3.3 \pm 0.1) \times 10^{35}$	-
Ω_Λ	0.76 ± 0.04	$0.761^{+0.017}_{-0.018}$
Ω_k	-0.002 ± 0.001	$-0.0030^{+0.0095}_{-0.0102}$
Ω_m	0.32 ± 0.02	$0.239^{+0.018}_{-0.017}$
Ω_r	$(3.2 \pm 0.2) \times 10^{-6}$	$(4.16) \times 10^{-6}$

TABLE II: We have calculated cosmological parameters using Equation 12 with $X(z) = 1$. We present the averaged results from our 10 runs of 100 steps each, we limited the search range available for the algorithm to avoid local minima. Literature values have also been provided for comparison. We conclude that we are able to produce consistent values inline with measured literature parameters.

Initially we chose to set $X(z) = 1$ as this represents simple ‘vanilla dark energy’ [9], later in our research we would find that there could be an alternative model to Λ CDM one where $X(z)$ is not unity. For the case of $X(z) = 1$, we believed a good starting point would be to use the same conditions of 1500 walks for 10 runs and not to limit the search space. Unsurprisingly the search became confined in local minima and the parameters generated were $\sim 40\%$ out from literature. To avoid these digressions, we reduced the number of walks to 100 steps and re-restricted the search space. We chose 100 as from the generated sets we could see that it was around this number that the experiment would

deviate and the inaccurate parameters would gain a higher likelihood.

Once confined we could produced results as found in Table II. Comparisons with the literature values allow us to find that our results are within range and agreement. Calculating a value for the reduced χ^2 we produced 2.4489 which is a small improvement on the least squares method and suggests a better fitting. However we further analysed the data to test whether we could accept this new method. One way which we did this was by calculating if there were any correlations between our generated parameters. We know that for some of our variables there should be a relationship, take Ω_Λ and Ω_m , they are related through the total density parameter as given by Equation 6. Looking at the calculated correlation values in Table III we find that in fact they have no connection, with -0.105 to have a correlation the correlation value should be -1 or 1 , and 0 for no relation [12]. Actually, bar with themselves, there appears to be little to no connection between the parameters.

Accordingly we must therefore remain skeptical in our results, whilst they appear to be in agreement with literature and the supernova data, with the issue of local minima at hand and with the problem of lack of correlation, more work such as implementing simulated annealing and alternative equations must be performed before we can begin to accept our values.

	L_{peak}	Ω_Λ	Ω_k	Ω_m	Ω_r
L_{peak}	+1.000	-0.088	+0.083	-0.213	-0.250
Ω_Λ	-0.088	+1.000	-0.113	-0.105	+0.128
Ω_k	+0.083	-0.113	+1.000	-0.107	-0.108
Ω_m	-0.213	-0.105	-0.107	+1.000	+0.004
Ω_r	-0.250	+0.128	-0.108	+0.004	+1.000

TABLE III: Correlation values have been calculated for the $X(z) = 1$ model data used to find the cosmological parameters as shown in Table II. Between the variables there is little correlation due to the independent random generation of them - correlation is found when the correlation value is ~ 1 or ~ -1 [12].

With our multi-parameter testing we then decided to explore the alternative picture where the dark energy density was not constant. We thus moved from the Λ CDM framework and introduced the concept of *quintessence*. The Quintessence Cold Dark Matter model (QCDM) explains the non-matter component of the total density as a ‘mixture of cold dark matter and quintessence’, where quintessence is a slowly-varying and spatially-inhomogeneous component [15]. An equation-of-state w can be attributed to this energy, where the negative pressure p and the density of the energy ρ can be related through $w = p/\rho$. By letting $X(z) = (1+z)^{3(1+w)}$ we can thus modify Equation 12 to account for quintessence [9]. In QCDM we find a potential range of $-1 < w \leq 0$, and comparatively $w = -1$ for Λ CDM [15] which produces the previously defined simplification of $X(z) = 1$.

Allowing our algorithm to additionally sample values for w we found that the results for the other parameters seem not to deviate too much from what we found previously. Viewable in Table I, w has just a 3% difference between the calculated number and the literature

value. This was a surprising result given that we expected larger deviations to the accuracy given what occurred when we first introduced the Λ CDM model.

Once we had our five cosmological parameters from QCDM, we used them to generate magnitudes of supernovae. Pairing this information with the Union2.1 data set we were able to compute $\chi^2_\nu = 2.4166$. We can compare this with our earlier least squares and Λ CDM work, we can say with some amount of confidence that there has been an improvement in the fitting due to the change in the model. The inclusion of w and the other parameters could be the reason for the enhancement, the model would now be a more accurate representation of the universe which in turn would provide a better fit to the observational data.

d. Closing Thoughts

In our work it has been possible to constrain the geometry of the universe through producing model redshifts and magnitudes. However we also had to make use of observational data such as Type Ia supernovae data sets [8, 11] and with constants such as Hubble's constant [16] and the speed of the light [17]. The key issue with employing these in our work is the uncertainty in the uncertainties. Whilst the observational data has errors quoted with their main values, more often than not it is difficult to source the origins of it and then to account for it within our own work. That is why for us to fully accept our cosmological parameters more work has to be done to quantify the extra systematic uncertainty.

When the uncertainties are further understood, one can then further explore different methods of constraining cosmological parameters. Other types of observational data could be utilised to provide results which would be independent of Type Ia supernovae. As a verification of our Λ CDM results, the Cosmic Microwave Background (CMB) data sets from the Planck Mission [18] could be utilised, additionally the Baryon Acoustic Oscillations (BAO) could also be employed to produce cosmic variables [11]. Then with all three sets of results together: Type Ia supernovae, CMB, and BAO we could then determine with confidence the total density parameter of the universe by superimposing the data and finding the location where the values meet [11].

III. CONCLUSIONS

In conclusion, we have found that it has been possible to constrain cosmological parameters of the universe using Type Ia supernova data and with statistical methods. We have used a basic least squares method and found that it is able to produce values for a single parameter which provide a reasonable fit for the Hubble diagram, we can produce a reduced χ^2 value of 2.4539. For more complex models with multiple parameters we had to employ an MCMC method, with our testing with a quintessence-based QCDM model we managed to produce a model which had $\chi^2_\nu = 2.4166$, a slight improvement to the least squares method.

More work definitely has to be done to improve our method for the multi-parameter fitting, in our testing with both Λ CDM and QCDM models we found that there was always a potential for the searcher algorithm to become trapped within local minima. That is simulated annealing should be implemented in future work

to avoid having to limit the parameter search space to avoid the wells.

Whilst we understand the importance of Type Ia supernovae as a tool for constraining cosmological variables, it would be beneficial if we could also produce separate results which made use of the cosmic microwave background and baryon acoustic oscillations. Then we would be more confident and better able to conclude what the cosmological parameters are as we could compare and contrast different results.

We will conclude on the fact that Type Ia supernovae must not be understated for their usefulness, they can be easily observed and their usage in cosmology
